Abstract

Objective: To determine eight parameters of oxidative stress markers in erythrocytes from children with sickle cell disease and compare with the same parameters in erythrocytes from healthy children, since oxidative stress plays an important role in the pathophysiology of sickle cell disease and because this disease is a serious public health problem in many countries.

Methods: Blood samples were obtained from 45 children with sickle cell disease (21 males and 24 females with a mean age of 9 years; range: 3–13 years) and 280 blood samples were obtained from children without hemoglobinopathies (137 males and 143 females with a mean age of 10 years; range: 8–11 years), as a control group. All blood samples were analyzed for methemoglobin, reduced glutathione, thiobarbituric acid reactive substances, percentage of hemolysis, reactive oxygen species, and activity of the enzymes glucose 6-phosphate dehydrogenase, superoxide dismutase, and catalase. Data were analyzed using Student's *t*-test and were expressed as the mean \pm standard deviation. A *p*-value of <0.05 was considered significant.

Results: Significant differences were observed between children with sickle cell disease and the control group for the parameters methemoglobin, thiobarbituric acid reactive substances, hemolysis, glucose 6-phosphate dehydrogenase activity, and reactive oxygen species, with higher levels in the patients than in the controls.

Marcadores de estresse oxidativo em eritrócitos de crianças com doença falciforme**Resumo**

Objetivo: Determinar parâmetros de estresse oxidativo em eritrócitos de crianças com doença falciforme e compará-los com os mesmos parâmetros em eritrócitos de crianças saudáveis, pois o estresse oxidativo desempenha um importante papel na fisiopatologia da doença falciforme, considerada um sério problema de saúde pública em muitos países.

Métodos: Foram obtidas amostras de sangue de 45 crianças com doença falciforme (21 meninos e 24 meninas com média de 9 anos, variação de 3 a 13 anos) e 280 amostras de sangue de crianças sem hemoglobinopatias (137 meninos e 143 meninas com média de 10 anos, variação de 8 a 11 anos), como grupo controle. Em todas as amostras foram determinados meta-hemoglobina, glutationa reduzida, substâncias reativas ao ácido tiobarbitúrico, porcentagem de hemólise, espécies reativas de oxigênio e atividade das enzimas glucose6-fosfato desidrogenase, superóxido dismutase e catalase. Os dados foram analisados com o teste *t* de Student e foram expressos como média ± desvio padrão. Um valor de *p* < 0,05 foi considerado significativo.

Resultados: Foram observadas diferenças significativas entre as crianças com doença falciforme e o grupo controle para os parâmetros meta-hemoglobina, substâncias reativas ao ácido tiobarbitúrico, porcentagem de hemólise, espécies reativas de oxigênio e atividade da enzima glucose6-fosfato desidrogenase, com níveis aumentados nos pacientes.

Conclusões: Foi possível determinar parâmetros de estresse oxidativo em eritrócitos de crianças, com técnicas laboratoriais simples e pequenos volumes de sangue. Esses biomarcadores podem ser úteis na avaliação da progressão e dos resultados de tratamentos da doença.

Introduction

Sickle cell disease is one of the most common hematologic disorders in the world and is a serious public health problem in many countries, including Brazil.¹ There are over 2 million Brazilian carriers of the sickle gene, and this disease is estimated to have an incidence of one in every 1000 live births. In 2001, a decree of the Ministry of Health included screening for hemoglobinopathies in the pre-existing screening programs.²

Sickle cell disease has been characterized as a multi-system disease, associated with episodes of acute illness and progressive organ damage, which begins in infancy and is primarily responsible for a shortened life expectancy in affected patients.³ Rates of morbidity and mortality are still high for patients with sickle cell disease. In Brazil, up to 25% of the children affected died during their first 5 years of life, but early diagnosis and treatment might reduce these rates and improve their quality of life.⁴

Sickle hemoglobin results from a substitution of glutamic acid to valine at the sixth amino acid position of the β-globin chain.⁵ This ostensibly minor change is the origin of hemoglobin S, and is responsible for significant changes in the stability and solubility of the molecule.⁶ The tendency of deoxygenated hemoglobin S to undergo polymerization underlies the innumerable expressions of the sickling syndromes with intravascular hemolysis.⁷ Free

plasma hemoglobin is able to initiate lipid peroxidation, and the heme, which readily dissociates from methemoglobin, may contribute significantly to oxidative stress,⁸ which might play a significant role in the pathophysiology of sickle cell disease-related microvascular dysfunction, vaso-occlusion, and development of organ damage.⁹ Biomarkers of oxidative stress can therefore be potentially useful, both to identify patients who are at high risk of oxidative damage and to evaluate the effects of anti-oxidative therapies.¹⁰

The purpose of this work was to evaluate the parameters of oxidative stress in erythrocytes from children with sickle cell disease, including percentages of hemolysis, methemoglobin, reduced glutathione, thiobarbituric acid-reactive substances, glucose 6-phosphate dehydrogenase activity, reactive oxygen species, and the anti-oxidant enzymes catalase and superoxide dismutase.

Methods

Chemicals

Meta-phosphoric acid, 2-mercaptoethanol, pyrogallol, 2,2-azobis(2-amidinopropane)hydrochloride (AAPH), ethylene-diaminetetraacetic acid (EDTA), and 5,5-dithiobiis-2-nitrobenzoic acid (DTNB) were obtained from Sigma-Aldrich (St. Louis, MO, USA). Sodium and potassium phosphates,

saponin, trichloroacetic acid, and thiobarbituric acid were supplied by Vetec Ltda (Rio de Janeiro, RJ, Brazil). Sodium citrate, tris(hydroxymethyl)aminomethane, and methanol were obtained from Merck (Darmstadt, Germany). G6-PD activity was determined using a PD410 kit by Randox Laboratories (Antrim, United Kingdom). All organic solvents were of high quality and were double-distilled, and all the other chemicals were of analytical grade.

Blood samples

Blood samples were obtained from 45 children diagnosed with sickle cell disease (21 males and 24 females with a mean age of 9 years; range: 3–13) at the hematopediaic department of Hospital de Clínicas, Universidade Federal do Paraná (UFPR). A control group consisted of 280 children without hemoglobinopathies (137 males and 143 females with a mean age of 10 years old; range: 8–11 years) who were participants of the university extension project entitled "Incidence of anemia and parasitic infections in school-aged children in municipal schools of metropolitan region of Curitiba-Paraná – Brazil," from UFPR. The use of human subjects was approved by the Ethical Committee for Research Involving Humans, Hospital de Clínicas, UFPR. Informed consent was obtained from the guardians for all the children. Children with any hematological alteration were excluded from the study.

A venous blood sample of 5 mL was collected from each patient in K3-EDTA coated tubes. Aliquots (200 µL) of whole blood were separated for determination of G6-PD activity. Then, samples were centrifuged at 3000 × g for 10 min. The plasma and the buffy coat were removed by aspiration, and the erythrocytes were washed with phosphate buffered saline (PBS) (NaCl, 150 mmol/L; NaH₂PO₄, 1.9 mmol/L; and Na₂HPO₄, 8.1 mmol/L) three times. Finally, red blood cells were suspended in PBS solution and water to obtain suspensions with hematocrits of approximately 10% and 40% for PBS solution and of approximately 40% for water solution. Hemoglobin concentration was measured in all suspensions. Not all analyses were performed in each specimen due to the limited volumes available.

Hematologic parameters

The complete blood count was determined using the Pentra 80 electronic cell counter (Horiba Medical, Japan).

Methemoglobin concentration

Methemoglobin concentration was determined according to a method based on Naoum et al.¹¹ adapted to small volumes. Aliquots (100 µL) of 10% erythrocyte suspensions were hemolyzed with 100 µL of 1% saponin and were stabilized in 1000 µL of 60 mmol/L phosphate buffer; the absorbance was then determined at 630 nm (for methemoglobin) and at 540 nm (for oxyhemoglobin). Methemoglobin concentration was expressed as a percentage in relation to hemoglobin concentration.

Reduced glutathione determination

Reduced glutathione (GSH) concentration was determined by a method previously described by Beutler,¹² by evaluating the reduction of 5,5'-dithiobis(2-nitrobenzoic acid) (DTNB) by sulfhydryl compounds from the formation of a yellow coloured anionic product whose absorbance was measured at 412 nm. Aliquots of 50 µL of 40% suspension of red blood cell in PBS were used. The GSH concentration was expressed in µmol/gHb.

Lipid peroxidation

Lipid peroxidation of red blood cell membranes was assessed based on Cesquini et al.¹³ Aliquots (600 µL) of a 10% suspension of red blood cell were added to 250 µL of 25% trichloroacetic acid and 600 µL of 1% thiobarbituric acid, boiled for 15 min at 100 °C, and cooled for 5 min at 0 °C. The absorbance of the thiobarbituric acid reactive substances (TBARS) formed was then read at 532 nm using ε = 156/(mmole cm) and the concentrations are expressed in nmol/gHb.

Measurement of hemolysis

Hemolysis of red blood cell was carried out as described by Banerjee et al.,¹⁴ adapted to microplates by mixing 10% suspension of red blood cell in PBS with varying amounts of AAPH solution (providing final concentrations of 50, 100, and 150 mmol/L). This reaction mixture was incubated for 3 h at 37 °C with shaking. The extent of hemolysis was determined spectrophotometrically by measuring the absorbance of the hemolysate at 540 nm in a microplate reader (Thermo Scientific, Thermo Plate, USA). Red blood cells in a solution of 200 mmol/L of AAPH were used as the 100% hemolysis control.

Activity of glucose6-phosphate dehydrogenase (G6-PD)

Aliquots (200 µL) of whole blood before erythrocyte isolation were washed with 2 mL PBS three times. G6-PD activity was determined using the Cobas Mira automated analyzer (Roche, Mannheim, Germany) with the PD410 commercial kit (Randox, Antrim, United Kingdom) as described in the manufacturer's manual.

Superoxide dismutase activity

The enzyme activity was based on a method adapted from Beutler¹² of the auto-oxidation of pyrogallol. Aliquots of 200 µL of packed red blood cell were hemolyzed with 300 µL of cold deionized water, and a chloroform-ethanol extract was prepared. The mixture was centrifuged at 2300 × g for 10 min. Varying amounts of the clear supernatant extract (0, 20, 40, 60, 80, 100 and 300 µL) were added to a solution of tris-HCl and water. After 10 min, 20 µL of a 1 mmol/L pyrogallol solution was added to each tube and the absorbance was measured at 412 nm in a microplate. The amount of

extract required to inhibit pyrogallol auto-oxidation by 50% was used to determine the level of enzyme activity.

Catalase activity

The enzyme activity was determined by a method adapted from Beutler¹² that measures the rate of decomposition of hydrogen peroxide by catalase spectrophotometrically at 240 nm. Aliquots of 50 μL of 40% suspension of red blood cell were added to 450 μL of a hemolyzing solution of β -mercaptoethanol (0.7 mmol/L) and EDTA (0.27 mol/L). This solution was diluted 1:100 in PBS and 10 μL of the final solution was added to 990 μL of hydrogen peroxide solution. The decrease in absorbance of the system was measured for 10 min.

Intracellular reactive oxygen species

Reactive oxygen species were determined according to a method based on López-Revuelta et al.¹⁵ adapted to small volumes of blood samples in a microplate. Erythrocytes (995 μL of 10%, v/v suspension in PBS) were incubated with 5 μL of dichlorodihydrofluorescein-diacetate (DCFDA, 10 mol/L) at 37 °C for 30 min. This suspension was diluted in 9.0 mL of PBS and 37.5 μL of this was then added to 112.5 μL of PBS in 96-well plates. Determination of reactive oxygen species was performed using a GloMax®-Multi Microplate Multimode Reader fluorimeter (Promega Corporation, USA). Under these conditions, DCFDA was hydrolyzed to 2',7'-dichlorodihydrofluorescein (DCFH₂), which then became available for oxidation by reactive oxygen species to produce fluorescent 2,7-dichlorofluorescein (DCF). Fluorescence was determined at 530 nm after excitation at 495 nm. Reactive oxygen species formation was expressed as fluorescence units (UF)/gHb.

Statistical analyses

Statistical analysis was performed using Statistica 8.0 software (StatSoft, USA). No outliers were identified. The Kolmogorov-Smirnov test was used to assess the normality and all parameters were distributed normally. Data

were expressed as mean \pm standard deviation and compared between groups using Student's *t*-test; a *p*-value <0.05 was considered significant.

Results

Data from blood counts of healthy children and patients with sickle cell disease are illustrated in Table 1. Statistically significant differences were observed for all parameters, except for medium corpuscular hemoglobin (MCH; *p* < 0.05).

Data from oxidative stress parameters are illustrated in Table 2, comparing patients with sickle cell disease with healthy children. Statistically significant differences were observed for methemoglobin, TBARS, percentage of hemolysis, G6-PD activity, and reactive oxygen species (*p* < 0.05).

Discussion

Normal erythrocytes suffer oxidative stress due to the production of reactive oxygen species that results from oxygen metabolism. However, this is efficiently repaired by the highly powerful antioxidant systems of the cell without any problematic effect. Oxidative stress occurs as a result of an imbalance between reactive oxygen species production and antioxidant defenses.¹⁶

In sickle cell disease, oxidative stress may result from high levels of meta hemoglobin S, which is less stable than meta hemoglobin A, leading to intravascular hemolysis,¹⁷ ischemia-reperfusion injury, chronic inflammation, and higher auto-oxidation of sickle hemoglobin.^{18,19} Many potential antioxidants are of interest in relation to sickle cell disease,²⁰ and several studies have demonstrated significant increases in stress markers and differing behavior in antioxidant defense systems in patients with sickle cell disease when compared to those in healthy subjects.²¹

The present results for blood counts confirm several features of sickle cell disease that are already known, such as the hemolytic anemia,²¹ evidenced by low levels of hemoglobin⁷ and increased levels of white blood cells and platelets.⁶

As previously demonstrated,⁸ methemoglobin levels are increased in individuals with sickle cell disease. There is

^b Percentages of hemolysis with addition of 0–150 mmol/L of AAPH solutions.

an electron transfer in the bonding interaction between the heme and the oxygen (O_2) in oxygenated hemoglobin. When hemoglobin deoxygenates, the heme iron normally remains in the ferrous state.²⁰ In this exchange, alterations wherein hemoglobin autoxidizes result in methemoglobin, with the heme iron in ferric state.⁸ Alterations in erythrocyte function or structure can lead to an enhanced flow of methemoglobin that can lead to oxidative stress.¹⁵

The increased intra- and extra-erythrocytic oxidative stress induces lipid peroxidation and membrane instability.¹⁴ TBARS is one of the existing biomarkers, and this evaluation is an indirect quantification of lipid peroxidation processes, which makes it a good indicator of pro-oxidant stimuli. In accordance with results reported previously,^{19,20,22} the present study observed significantly higher levels of TBARS in patients with sickle cell disease than in the controls.

Rigid and deformed sickle erythrocytes have a shortened lifespan and undergo both intravascular and extravascular hemolysis.²³ Higher percentages of hemolysis in erythrocyte from children with sickle cell disease than in the control group were observed, both in basal suspensions of erythrocytes and in suspensions incubated with an oxidizing agent.

G6-PD is an important enzyme related to the antioxidant defense in erythrocytes.²⁰ Higher activity of this enzyme in patients with sickle cell disease was found than in the control group. It was previously reported that erythrocytes from patients with sickle cell disease have an increased percentage of reticulocytes, while the activity of G6-PD in reticulocytes is normal, but declines exponentially as the red cells age.²⁴

Sickle cells spontaneously generate approximately two times more reactive oxygen species than normal red blood cells.²⁵ In accordance with the findings of George et al.,²⁶ elevated levels of reactive oxygen species in sickle erythrocytes were also demonstrated.

Reduced glutathione (GSH) is present at high concentrations in erythrocytes and acts by itself or via glutathione peroxidase as a major reducing source to maintain cell integrity.¹⁷ The measurements of GSH and its oxidized form

glutathione disulfide (GSSG) have been considered useful indicators of *in vivo* oxidative stress.²⁷ The majority of studies of adults with sickle cell disease reported some deficits of endogenous synthesis of GSH, probably due to its consumption by increased oxidant production.^{26,28} Although Rusanova et al.²² showed high levels of GSH in pediatric patients with sickle cell disease, the present study found no difference in GSH levels between children with sickle cell disease and the control group.

Superoxide dismutase can convert superoxide to hydrogen peroxide, and catalase can remove excess hydrogen peroxide.¹⁶ According to Silva et al.,²⁰ the increased pro-oxidant generation in sickle cell disease results in an antioxidant deficiency. However, there are some discrepancies between studies on superoxide dismutase and catalase levels in this disease, with some studies observing increased activity and others observing decreased levels.²⁹ An increase in these enzymes activity potentially constitutes a defense mechanism in response to increased oxidative stress,¹⁹ or might be a consequence of increased reticulocyte content in blood samples from patients with sickle cell disease. However, a decrease in enzyme levels was related to disease severity in patients.^{20,22} These seemingly contradictory findings could be due to differences in the extent of oxidative stress, disease severity, enzyme polymorphism, and the enzyme co-factor.²⁹ The present results showed no difference between the activities of these enzymes in children with sickle cell disease and those in healthy children, according with Cho et al.³⁰ with regard to catalase. These results may be due to large individual variability found among patients.

In light of evidence suggesting that an excess of oxidative stress has implications in sickle cell disease pathophysiology, the assessment of oxidative stress parameters in these patients may provide useful information regarding the use of current medications and may lead to the development of new therapeutic strategies.^{10,19,20} Monitoring the oxidative stress involves the observation of different parameters associated with pro-oxidant and antioxidant biomarkers.²⁷

However, the use of an isolated biomarker and the measurement of individual antioxidants are not likely to be useful indexes of oxidative status. The oxidant–antioxidant balance involves biochemical reactions that require the evaluation of many endpoints.²⁶

The present study evaluated eight oxidative stress markers, including pro-oxidant and antioxidant parameters. The results indicate the presence of a hyperoxidative status in children with sickle cell disease, which can be observed by their high levels of methemoglobin, TBARS, hemolysis, reactive oxygen species, and G6-PD activity. Simple techniques were used to determine these parameters using small volumes of blood. These parameters that appeared altered in children with sickle cell disease can be useful in the evaluation of disease progression and treatment.
